Abstract

Motivation: Technological advancements in high-throughput DNA sequencing have led to an exponential growth of sequencing data being produced and stored as a byproduct of biomedical research. Despite its public availability, a majority of this data remains hard to query to the research community due to a lack of efficient data representation and indexing solutions. One of the available techniques to represent read data is a condensed form as an assembly graph. Such a representation contains all sequence information but does not store contextual information and metadata.

Results: We present two new approaches for a compressed representation of a graph coloring: a lossless compression scheme based on a novel application of wavelet tries as well as a highly accurate lossy compression based on a set of Bloom filters. Both strategies retain a coloring with dynamically changing graph topology. We present construction and merge procedures for both methods and evaluate their performance on a wide range of different datasets. By dropping the requirement of a fully lossless compression and using the topological information of the underlying graph, we can reduce memory requirements by up to three orders of magnitude. Representing individual colors as independently stored modules, our approaches are fully dynamic and can be efficiently parallelized. These properties allow for an easy upscaling to the problem sizes common to the biomedical domain.

Availability: We provide prototype implementations in C++, summaries of our experiments as well as links to all datasets publicly at https://github.com/ratschlab/graph_annotation.

1 Introduction

The revolution of high-throughput DNA sequencing has created an unprecedented need for efficient representations of large amounts of biological sequences. In the next five years alone, the global sequencing capacity is estimated to exceed one exabyte (Stephens et al., 2016). While a large fraction of this capacity will be used for clinical and human genome sequencing, such as the 1000 Genomes Project (Auton et al., 2015) or the UK10K (Walter et al., 2015) effort, that are well suited for reference-based compression methods, the remaining amount is dauntingly large. This remainder does not only include sequences of model and non-model organisms (Zhang et al., 2015) but also community approaches such as whole metagenome sequencing (WMS) (Turnbaugh et al., 2007; Ehrlich and Consortium, 2011).

The next logical steps of data integration for genome sequencing projects are assembly graphs that help to gather short sequence reads into genomic contigs and eventually draft genomes. While assembly of a single species genome is already a challenging task (Bradnam et al., 2013), assembling a set of genomes from one or many WMS samples is even more difficult. Although preprocessing methods such as taxonomic binning (Dröge and McHardy, 2012) help to reduce its complexity, the task remains a challenge. A commonly used strategy to generate sequence assemblies is based on de Bruijn graphs that collapse redundant sequence information into a node set of unique substrings of length k (k-mers) and transform the assembly problem into the problem of finding an Eulerian path in the graph (Pevzner et al., 2001).

Especially in a co-assembly setting, where a mixture of multiple source sequence sets is combined and information in addition to the sequences needs to be stored, colored de Bruijn graphs form a suitable data structure, as they allow association of multiple colors with each node or edge (Iqbal et al., 2012). A second use case is the application of such graphs for the efficient representation and indexing of multiple...
Owing to the large size, and, subsequently, the excessive memory footprints of such graphs, recent work has suggested compressed representations for de Bruijn graphs based on approximate membership query (AMQ) data structures ([Shahikh and Inkik, 2011] [Bunno et al., 2015]) or generalizations of the Burrows-Wheeler transform to graphs ([Bowe et al., 2012]). The recent work on compressed colored de Bruijn graphs has followed this trend. Currently, there exist two distinct paradigms. The first is to compress the complete colored graph in a single data structure while the second proposes two separate (compressed) representations of graph and coloring. Approaches that fall in the first demonstrate good performance on small datasets but require prohibitive memory for larger genomes. The second group contains approaches such as [Almodaresi et al., 2017], that re-purposes the count annotation matrix and shows excellent compression rates.

2 Approach

The proposed techniques for color compression take advantage of the underlying sequence graph. Although we impose no restrictions on graph topology, we assume that all nodes in a linear path (a directed path in which all nodes have in-degree and out-degree 1) share an identical coloring (a set of colors). In this work, we will focus on compressing colorings of de Bruijn graphs constructed on pan-genomic and metagenomic datasets.

We implement our reference metagenome as a colored de Bruijn graph (cDBK), which consists of a de Bruijn graph constructed from a collection of input sequences (forward and reverse complement) and an annotation associated with the k-mers generated from these input sequences. We represent this annotation as a binary matrix, where each row corresponds to an edge and each column corresponds to a predefined annotation class. Set bits in this matrix indicate associations of edges with annotation classes.

2.1 Preliminaries and notation

Let $\Sigma$ be an alphabet of fixed size (in the case of genome graphs, $\Sigma = \{A, C, G, T\}$, where $S$ represents the string terminator). Given a string $s \in \Sigma^*$, we use $s[i : j]$ to denote the substring of $s$ from index $i$ up to and including index $j$, with $i, j \geq 1$.

Given a bit vector $b \in \{0, 1\}^m$ of length $m$, we use the notation $|b|$ to refer to its length, $b[i]$ to refer to its $i$th character, $1 \leq i \leq |b|$, $b[i : k]$ to refer to the bit vector $b[j] \cdots b[k]$, $b[i : k]$ to refer to its prefix $b[1 : k]$, and $b[j : ]$ to refer to its suffix $b[j : ]$. The empty vector is denoted $\epsilon$.

Finally, given bit vectors $a, b \in \{0, 1\}^m$, we use the notation $a \lor b$ and $a \land b$ to denote the bitwise OR and AND operators, respectively.

The function $\text{rank}(b, j)$ counts the occurrences of the character $0$ in the prefix $b[j : ]$, while $\text{select}(b, j)$ returns the index of the $j$th $0$ in $b$. The functions $\text{rank}$ and $\text{select}$ are defined analogously for the $1$ character. We will use the notation $2^d$ to denote the power set of a set $A$ and abuse the notation $|\cdot|$ to also denote set cardinalities.

2.2 Graph representation

Given an ordering of the edges $E = \{e_1, \ldots, e_n\}$ of an underlying graph $G = (V, E)$ and a set of colors $\{1, \ldots, m\}$, we define the annotation matrix $A \in \{0, 1\}^{n \times m}$ such that

$$A_{ij} = \begin{cases} 1, & e_i \text{ has color } j, \\ 0, & \text{otherwise.} \end{cases} \quad (1)$$

As a proof of concept for the graph coloring presented in this work, and without loss of generality, we use a simple
representation of a de Bruijn graph with its edges (the k-mers) stored in a hash table.

During construction of the graph, colors are computed for each node based on the metadata of the input sequences. We assign each unique metadata string to an annotation matrix \( A \) with \( k \) of colors encoding its respective metadata categories. We stored in a hash table the \( k \) observed during construction. The resulting graph combines the \( k \)-mers are collected to construct graph edges, we combine the \( k \)-mers’ respective bit vectors via bit-wise OR operations and assign the aggregated coloring to the resulting edge. Alongside the de Bruijn graph, this process results in a graph coloring as an annotation matrix \( A \) with \( n \) rows corresponding to the edges of the graph and \( m \) columns corresponding to the total number of annotation classes observed during construction. The resulting graph-coloring pair \( (G, A) \) is a colored de Bruijn graph. When the graph is queried, patterns are mapped to a path (a sequence of edges) and, hence, a corresponding sequence of annotation matrix rows.

2.3 Graph topology-aided color compression

2.3.1 Loss-less row compression with wavelet tries

For lossless compression of annotation matrices, we propose a novel application of the wavelet trie data structure [Gross and Ottaviano 2012]. Wavelet tries compress tuples of dynamic bit vectors by finding common segments (contiguous subsequences) among the encodings of its characters. Briefly, a wavelet trie builds on the concept of a wavelet tree and takes the shape of a compact prefix tree (a binary radix trie, cf. Figure B and Suppl. Figure 5).

In the context of genome graph coloring, we employ wavelet tries to compress the rows of the annotation matrix to allow for dynamic updates in its rows and columns. We employ a construction strategy based on wavelet trie merging [Gross and Ottaviano 2012; Böttcher et al. 2017], but in a parallel fashion. Since wavelet tries were originally conceived to compress binary encodings of strings (where the null terminal character has an encoding), the assumption that the end of a sequence is marked by a specific subsequence no longer holds in our application. Thus, our construction and merging algorithms are adapted to take this fact into account.

**Construction**

The wavelet trie encoding the annotation matrix \( A \in \{0,1\}^{n \times m} \) is constructed recursively and is a binary tree (Figure 4) with nodes \( V_F \) of the form

\[ (\alpha_j, \beta_j) \in V_F \quad \alpha_j, \beta_j \in \{0,1\}^* \]

The \( \alpha_j \) are referred to as the *longest common prefixes* (LCPs) and the \( \beta_j \) are referred to as the *assignment vectors*.

We define the initial tuple of input bit vectors to be the rows of \( A \), \( B = (A^1, \ldots, A^m) \), where \( A^i = (A^i_1, \ldots, A^i_n) \in \{0,1\}^n \), \( 1 \leq i \leq n \). The algorithm starts by constructing the root node \((\alpha_1, \beta_1)\) from the initial set of input vectors \( B_1 = B \).

On the \( j \)th iteration, for a list of input bit vectors

\[ B_j = (b^j_1, \ldots, b^j_{\ell_j}), \quad b^j_i \in \{0,1\}^{b_i} \quad 1 \leq i \leq \ell_j \]

we compute \((\alpha_j, \beta_j)\) as follows. First, we compute the longest common prefix \( \alpha_j := \text{LCP}(B_j) \) for the bit vectors in \( B_j \). Formally, this function is defined as follows,

\[ \text{LCP}(B_j) = \arg \max \{ \alpha \in \{0,1\}^* | b^j_1[\alpha] = b^j_2[\alpha] = \ldots = b^j_{\ell_j}[\alpha] \} \]

If the computed \( \alpha_j \) matches all the input bit vectors, let the assignment vector consist of \( \beta_j = (0, \ldots, 0) \) and \((\alpha_j, \beta_j)\) is referred to as a *leaf*, which terminates the recursion branch. Otherwise, the assignment vector is set to be the concatenation of next bits in each of the \( b^j_i \), \( 1 \leq i \leq \ell_j \), after removing the common prefix \( \alpha_j \).

\[ \beta_j := (b^j_1[\alpha_j] + 1, \ldots, b^j_{\ell_j}[\alpha_j] + 1) \]

We continue the recursion on the child nodes \((\alpha_{j+1}, \beta_{j+1})\) and \((\alpha_{j+2}, \beta_{j+2})\), with the new tuples of bit vectors \( B_{j+1} \) and \( B_{j+2} \), respectively, which are defined by partitioning \( B_j \) based on the assignments \( \beta_j \) and removing the first \( |\alpha_j| + 1 \) bits.

\[ B_{j+1} := (b^{\text{select}}_{j+1}(\beta_j)[|\alpha_j| + 2], \ldots, b^{\text{select}}_{j+1}(\beta_j)[|\alpha_j| + 2]) \]

\[ B_{j+2} := (b^{\text{select}}_{j+1}(\beta_j)[|\alpha_j| + 2], \ldots, b^{\text{select}}_{j+1}(\beta_j)[|\alpha_j| + 2]) \]

**Parallel construction via trie merging**

To allow for parallel construction, we develop an algorithm to merge wavelet tries constructed on batches of edge colorings that generalizes the methods presented by [Gross and Ottaviano 2012] and [Böttcher et al. 2017]. Merging proceeds by performing an *align* and a *merge* step on each node, starting from the root (Suppl. Figure S2). Given two wavelet tries \( T' \) and \( T'' \) with node sets \( V_{T'} \) and \( V_{T''} \), \( \{\alpha'_i, \beta'_i\} \subseteq V_{T'} \) and \( \{\alpha''_i, \beta''_i\} \subseteq V_{T''} \), that we want to merge into a new trie \( T \), the merging process can be summarized in three steps:

1. **Align:** For the nodes \( \{\alpha'_i, \beta'_i\} \) and \( \{\alpha''_i, \beta''_i\} \), compute the longest common prefix \( \text{LCP}(\alpha'_i, \beta'_i) \), create new nodes with this value and appropriate \( \beta \) vectors, and set this to be the parent of the current nodes.
2. **Merge:** Once \( \alpha'_i \) and \( \alpha''_i \) are equal, concatenate \( \beta'_i \) and \( \beta''_i \).
3. **Repeat:** Move down to \( j \)'s children and apply the same function until all leaves are reached.

**Time complexity**

Let \( A \in \{0,1\}^{n \times m} \) be the annotation matrix. The height of a constructed wavelet trie with nodes \( V_F \) depends on the degree to which the input bit vectors share common prefixes. Since there can be at most \( n \) leaves, and the maximum height of the trie is at most \( m \), the number of nodes can be at most \( |V_F| \leq \min(2n, 2^m - 1) \).
constructed, queries can be performed in $O(h)$ time (Grossi and Ottaviano, 2012). Once a wavelet trie is built, the common prefix of the bit vectors is extracted at a node, the common prefix of the bit vectors is extracted and used to form groups of similarly colored edges and help optimize compression ratios.

Using prior knowledge to improve compression One of the most important factors determining compression ratio (see Section 2.3.2 for a formal definition) of a wavelet trie is the distribution of longest common prefixes encountered during construction. We explore whether prior knowledge can be used to form groups of similarly colored edges and help optimize compression ratios.

Given two wavelet tries with sets of nodes $V_T'$ and $V_T''$, merging is performed in $O(|V_T'| + |V_T''| + |\beta_T'| + |\beta_T''|)$ time (Grossi and Ottaviano, 2012). Once a wavelet trie is built, queries can be performed in $O(h)$ time, where $h \leq m$ is the height of the trie. To achieve this value, the $\beta_T$ are compressed with RRR coding (Raman et al., 2007) to support rank operations in $O(1)$ time.

### 2.3.2 Probabilistic column compression with Bloom filters

For cases where a lossy compression scheme with moderate loss of accuracy will suffice in place of fully lossless compression, we explore a probabilistic compression of the annotation matrix as a near-exact compromise. Since, by definition, the columns of the annotation matrix encode set membership, it is possible to compress them using Bloom filters (Bloom, 1970), a probabilistic data structure for approximate set membership queries.

A Bloom filter is a tuple $BF = (B, H)$, where $B \in \{0, 1\}^b$ is a bit vector and $H = \{h_1, \ldots, h_d\}$ is a collection of $d$ hash functions mapping each input to an element of $\{1, \ldots, b\}$. For simplicity of notation, let $e_i \in \{0, 1\}^b$ denote a bit vector in which only the $i^{th}$ bit is set to one.

Two of the operations supported on this structure are insert and the relation of approximate membership $\in$,

$$insert((B, H), x) = (B \lor e_{h_1(x)} \lor \cdots \lor e_{h_d(x)}; H),$$

$$x \in BF \iff insert(BF, x) = BF.$$  

Bloom filter reparametrization Although the Bloom filter has no false negative errors, the false positive probability (FPP) of the approximate membership query on a Bloom filter with $s$ inserted elements can be approximated as (Mitzenmacher, 2001)

$$FPP(b, d, s) = \left(1 - \left(1 - \frac{1}{b}\right)^d\right)^s \approx \left(1 - e^{-\frac{s}{b}}\right)^d.$$  

As a corollary, an alternate parametrization of Bloom filters can be derived. Given a target false positive probability $p$ and $s$ elements to insert, optimal values for $d$ and $b$ are

$$d = \left[\log_2 p\right],$$

$$b = \frac{\log_2 p}{\ln 2 \cdot s}.$$  

Given an encoding of an annotation matrix $A \in \{0, 1\}^{n \times m}$ as a collection of Bloom filters $BF_1, \ldots, BF_m$, the raw annotation of an edge $e_i \in E$ being queried is as follows:

$$query(e_i) = (1_{(e_i \in BF_1)} \cdots 1_{(e_i \in BF_m)}).$$  

Neighborhood-based Bloom filter correction Following the same rationale as for the wavelet tries, and building on the assumption that edges neighboring in the graph often share a large part of their annotation, we can also drastically improve the compression power of the Bloom filters.

More precisely, given a linear path, we compute the intersection of the colorings of edges in some neighborhood within the path and obtain an annotation with drastically reduced FPP. If we let $A(e) \subseteq E$ denote the neighborhood of an edge $e \in E$ within a linear path in which all nodes are
We use several standard datasets to evaluate the performance of our compression schemes. They originate either from viruses (Virus100, Virus1000, and Virus50000), bacteria (Lactobacillus) or humans (chr22+gnomAD and hg19+gnomAD) and are chosen to test the methods on different coloring distributions, sizes and densities. They further reflect varying graph topologies and allow us to study the effect of topology-informed compression in a robust testbed. We construct de Bruijn graphs of order \( f \) to reflect varying graph topologies and allow us to derive different coloring distributions, sizes and densities. They are additionally colored by their corresponding reference chromosomes and the ethnic groups present in the gnomAD data. The colors corresponding to reference chromosomes are designated as the class indicators without adding additional columns (i.e., the sequence variant edges are additionally colored by their corresponding reference chromosome colors).

Table 1 summarizes these collections in terms of their number of nodes and edges for the constructed de Bruijn graphs, as well as their respective numbers of colors and unique colorings derived from the corresponding metadata.

### 3 Evaluation and Applications

In this section, we explore our hypothesis that graph topology can aid in improving compression ratios and study the space complexities of our compression techniques on a variety of viral datasets increasing in size. Finally, we compare the compression ratios of our methods to those of general compression algorithms and those of methods developed specifically for de Bruijn graph color compression.

Experiments were performed on a single thread for Bloom filter compression and ten threads for wavelet trie compression, on the Intel(R) Xeon(R) CPU E5-2697 v4 (2.30GHz) cores of ETH’s shared high-performance compute systems. Run times and peak RAM consumption are reported in Suppl. Table S7.

#### 3.1 Graph topology affects compression ratios

For both the wavelet trie and Bloom filter compression schemes, we explored methods for encoding graph topology with the goal of improving compression ratios. To this end, we explore the introduction of additional class indicator colors/bits for wavelet tries and graph neighborhood-based annotation correction for Bloom filters.

#### 3.1.1 Class indicator bits significantly improve compression ratio

We test the hypothesis that optimal compression can be achieved by setting class indicator bits in low-index positions in annotation matrix columns via an exact test by permuting the annotation matrix column order on the Virus100 and Lactobacillus datasets. More precisely, we assume to share the same annotation, we can then define the corrected annotation as

\[
\text{annotation}(e) = \text{query}(e) \land \bigwedge_{s' \in N(e)} \text{query}(e').
\]  

Following the argument in (Mitzenmacher, 2001) (see Formula 6), the FPP for one annotation color of a segment of length \( \ell \) can be approximated as

\[
\text{FPP}(b, d, s) \approx (1 - e^{-bt})^{ds},
\]

since \( \ell \) false positive errors have to be made to lead the Bloom filter to a false positive error.

This correction method relies on direct access to the underlying graph structure to reference during decoding, in contrast to the wavelet trie approach in which this is not required.

#### 4.4 Data

We use several standard datasets to evaluate the performance of our compression schemes. They originate either from viruses (Virus100, Virus1000, and Virus50000), bacteria (Lactobacillus) or humans (chr22+gnomAD and hg19+gnomAD) and are chosen to test the methods on different coloring distributions, sizes and densities. They further reflect varying graph topologies and allow us to study the effect of topology-informed compression in a robust testbed. We construct de Bruijn graphs of order \( f \) to reflect varying graph topologies and allow us to derive different coloring distributions, sizes and densities. They are additionally colored by their corresponding reference chromosomes and the ethnic groups present in the gnomAD data. The colors corresponding to reference chromosomes are designated as the class indicators without adding additional columns (i.e., the sequence variant edges are additionally colored by their corresponding reference chromosome colors).

Table 1 summarizes these collections in terms of their number of nodes and edges for the constructed de Bruijn graphs, as well as their respective numbers of colors and unique colorings derived from the corresponding metadata.

### 3 Evaluation and Applications

In this section, we explore our hypothesis that graph topology can aid in improving compression ratios and study the space complexities of our compression techniques on a variety of viral datasets increasing in size. Finally, we compare the compression ratios of our methods to those of general compression algorithms and those of methods developed specifically for de Bruijn graph color compression.

Experiments were performed on a single thread for Bloom filter compression and ten threads for wavelet trie compression, on the Intel(R) Xeon(R) CPU E5-2697 v4 (2.30GHz) cores of ETH’s shared high-performance compute systems. Run times and peak RAM consumption are reported in Suppl. Table S7.

#### 3.1.1 Class indicator bits significantly improve compression ratio

We test the hypothesis that optimal compression can be achieved by setting class indicator bits in low-index positions in annotation matrix columns via an exact test by permuting the annotation matrix column order on the Virus100 and Lactobacillus datasets. More precisely, we assume to share the same annotation, we can then define the corrected annotation as

\[
\text{annotation}(e) = \text{query}(e) \land \bigwedge_{s' \in N(e)} \text{query}(e').
\]  

Following the argument in (Mitzenmacher, 2001) (see Formula 6), the FPP for one annotation color of a segment of length \( \ell \) can be approximated as

\[
\text{FPP}(b, d, s) \approx (1 - e^{-bt})^{ds},
\]

since \( \ell \) false positive errors have to be made to lead the Bloom filter to a false positive error.

This correction method relies on direct access to the underlying graph structure to reference during decoding, in contrast to the wavelet trie approach in which this is not required.

#### 4.4 Data

We use several standard datasets to evaluate the performance of our compression schemes. They originate either from viruses (Virus100, Virus1000, and Virus50000), bacteria (Lactobacillus) or humans (chr22+gnomAD and hg19+gnomAD) and are chosen to test the methods on different coloring distributions, sizes and densities. They further reflect varying graph topologies and allow us to study the effect of topology-informed compression in a robust testbed. We construct de Bruijn graphs of order \( f \) to reflect varying graph topologies and allow us to derive different coloring distributions, sizes and densities. They are additionally colored by their corresponding reference chromosomes and the ethnic groups present in the gnomAD data. The colors corresponding to reference chromosomes are designated as the class indicators without adding additional columns (i.e., the sequence variant edges are additionally colored by their corresponding reference chromosome colors).

Table 1 summarizes these collections in terms of their number of nodes and edges for the constructed de Bruijn graphs, as well as their respective numbers of colors and unique colorings derived from the corresponding metadata.
generate 100 samples by randomly permuting the columns in the annotation matrix and compress the resulting data to approximate the null distribution of compression file sizes across permutations of the matrix column order (see Figure 2a).

First, we test the hypothesis without setting class indicator bits, the compressed file size corresponding to the column ordering induced by the graph construction algorithm is found to not be optimal with respect to its approximated null distribution (see Suppl. Figure S-3). However, when class indicator bits are set in low index positions, the original ordering of columns is optimal with respect to its approximated null distribution (see Suppl. Figure S-3). However, when class indicator bits are set in low index positions, the original ordering of columns is optimal with respect to its approximated null distribution, resulting in an empirical p-value of p < 0.01 (see Figure 2a).

3.1.2 Neighborhood correction improves Bloom filter compression ratio 30- to 70-fold
We study the effects of neighborhood-based Bloom filter correction on all datasets by varying the average number of bits per edge of the Bloom filters and measuring the accuracy of color reconstruction (see Methods, Section 2.3.2). The results show 70-fold decreases in the number of bits required per edge to achieve similar decompression accuracies on almost all datasets (see Figure 2b). A notable exception is the chr22 dataset, where only a 30-fold improvement is observed.

The average number of graph traversal steps needed to correct the Bloom filters to an accuracy of 95% ranges from 99.1 to 207.3 (see Suppl. Table S-1). To correct the Bloom filters to an accuracy of 99%, the average number of traversal steps required ranges from 82.3 to 156.3.

3.2 Compression power grows with the number of colors
To test the scalability of the compression methods, we generate a chain (a linear hierarchy) of virus graphs ranging from 100 to 1000 randomly selected genomes in steps of 100 (i.e., $G_1 \subset \cdots \subset G_{10}$) and measure the compression ratios of the annotations for each graph. On our datasets, the wavelet trie method with class indicator bits set and the Bloom filter method with FPP < 0.05 display linear growth in the compression ratio as number of genomes increases to 1000 genomes (see Suppl. Figure S-4), with sublinear growth for more genomes (see Figure 3). Sublinear growth is observed in the wavelet trie method without class indicator bits and, to a lesser extent, the Bloom filter method.

Table 1. Datasets used for evaluation

Columns represent number of nodes and edges per dataset, total number of colors and annotations (number of unique edge colorings, or color combinations), and density of the annotation matrices, where the quantity s refers to the number of set bits in the annotation matrices.

Fig. 2: Graph topology improves compression ratios (a) Distribution of the file sizes of wavelet tries over 100 random permutations of the annotation matrix column order. The original ordering of the columns leads to an optimal file size when class indicator bits are set, as indicated in the CDF by the red dot. (b) Bloom filter decompression accuracy (fraction of correct edge colors) as a function of filter size (bits per edge). Parameters required to achieve 99% accuracy on the uncorrected Bloom filters were not computed.
with FPP < 0.01 (see Figure 2 and Suppl. Figure S-1). A two-fold decrease in compression ratio is observed when the false positive probability criterion for the Bloom filters is decreased from 0.05 to 0.01.

3.3 Wavelet tries and Bloom filters improve on state-of-the-art compression ratios

Finally, we close with a side-by-side comparison of the various de Bruijn graph color compression schemes presented in Section 3. In addition to these domain-specific methods, we include two popular general-purpose static compression methods, gzip and bzip2. gzip is an implementation of the LZW algorithm that encodes blocks of text, while bzip2 performs a sequence of transformations, including run-length encoding, BWT, move-to-front transforms, and Huffman coding.

Table 2 lists the number of bits required per edge to compress our experimental collections.

3.3.1 Wavelet trie compression ratios match state-of-the-art

Our results show that wavelet trie compression outperforms gzip and the VAR method on most datasets, while performing marginally better than Rainbowfish and marginally worse than bzip2 (see Table 2). The Virus100, Virus1000, Virus50000, and Lactobacillus datasets are compressed to 5.8, 23.8, 698.4, and 7.3 bits per edge, respectively. The Virus1000 and Virus50000 datasets are notable in that wavelet tries without indicator bits set exhibit the worst compression performance among the tested methods. Setting class indicator bits leads to a two-fold improvement in the compression performance on the Virus1000 dataset (from 23.8 bits per edge to 10.5). ten-fold improvement on the Virus50000 dataset (from 698.4 to 73.7 bits per edge), and marginal improvements in performance on the other datasets (4.9 and 5.6 bits per edge on the Virus100 and Lactobacillus datasets, respectively). In this setting, the chr22+gnomAD and hg19+gnomAD datasets are compressed to 2.4 and 5.5 bits per edge.

3.3.2 Bloom filters improve on state-of-the-art by an order of magnitude

At an accuracy of 95%, our method is considerably more space efficient, achieving compression ratios over an order of magnitude greater than bzip2 and Rainbowfish. An average of 0.35 and 0.49 bits per edge are required to compress the Virus100 and Virus1000 datasets, respectively, compared to 5.8 and 9.7 bits for Rainbowfish and 4.8 and 7.5 bits for bzip2. An average of 2.4 bits per edge are required to compress the Virus50000 data set, compared to 37.7 bits for bzip2. We were unable to compress this dataset using the Rainbowfish method due to its RAM consumption exceeding the per-job limit on our computing system. On the Lactobacillus dataset, an average of 1 bit per edge are required, compared to 7.8 bits for Rainbowfish and 5.7 bits for bzip2. On the chr22+gnomAD and hg19+gnomAD datasets, 0.45 and 0.68 bits are required per edge, compared to 2.7 and 5.4 bits for bzip2, and 3.3 and 5.6 bits for Rainbowfish.

At 99% accuracy, an increasing number of bits are required per edge with increased virus dataset size (see Table 2). Fold-increases in the number of bits per edge from 1.3 bits (Virus100) to 5.4 bits (chr22+gnomAD) are required.

4 Discussion

In this study, we have addressed the problem of encoding metadata as edge colors of a given graph and demonstrated its application to de Bruijn graphs by presenting two distinct compression schemes. First, we have developed a novel application and extended parallel construction method of the wavelet trie data structure on general sequences of bit vectors that employs an iterative merging scheme to build larger tries from many smaller instances. Further, we have presented a probabilistic, compressed representation using approximate set representations that can store an arbitrary amount of annotations on the graph and allows for greater compression ratios by taking advantage of information shared between neighboring nodes to correct errors.

We have shown that utilizing the topology of the underlying graph helps in achieving improved compression rates. For the wavelet tries, we used indicators for the backbone regions of the de Bruijn graph positioned in low-index columns of the annotation matrix and for the Bloom filter approach, we used neighboring linear regions in the graph for error correction. Either representation can be efficiently decompressed and queried to retrieve the coloring of arbitrary paths in the graph. Although it is helpful to know the frequency of individual colors upfront to design an optimal order of columns for the wavelet trie compression or to optimally choose the size of the individual Bloom filters used, these parameters can be easily estimated from a subsample of the input data, allowing to directly build the full coloring.
We have shown the utility of our approaches on different biological datasets, including data from virus, bacteria and human genomes, representing different classes of graph topologies and colorings. On all datasets we achieve comparable or strongly increased compression performance at very high levels of decompression accuracy. Notably, our approach is dynamic and allows for an easy extension with additional labels/colors or for changes in the underlying graph structures, enabling the augmentation of large colored graphs with new annotations — a scenario commonly occurring in the genomics setting. Additionally, the wavelet trie model is fully dynamic, allowing for label and edge removal.

A possible limitation of the wavelet trie method is its reliance on shared segments (contiguous subsequences), especially in the first few columns of the annotation matrix, to effectively partition the rows for optimal compression. The results on the viral data sets confirm that, given an annotation matrix with very sparse and mutually-exclusive rows, wavelet tries underperform relative to other methods due to tree imbalance. While this is partially addressed by setting class indicator bits in the annotation matrix, a more principled approach with less user input will become necessary in future work and could involve an analysis of the de Bruijn graph topology to algorithmically determine optimal backbone paths. Further improvements in compression ratio could be gained by an optimal ordering of the rows of the annotation matrix, but at the additional cost of maintaining a map from graph coordinates to their respective annotation matrix rows.

One of the limitations of our Bloom filter correction method is its reliance on the presence of long, identically-colored paths for correction. While this assumption worked well for the Virus100 and Virus1000 datasets, the shorter linear paths in the larger sets reduced our ability to correct errors in this fashion. Despite its higher compression ratio, one restriction of the Bloom filter-based method is that its corresponding graph must be accessible for reference. Although this is already done in our application, it couples annotation query times to graph query times. To decouple the graph from the filters, an additional structure could be constructed to indicate edges in the graph at which changes in coloring occur. Such a structure would then allow for the assumption that colors remain constant in linear regions to be relaxed.

Future work on probabilistic compression will focus on improving scaling properties. In a dynamic setting, if a dataset grows rapidly in the number of edges, the decoding accuracy will eventually drop, ultimately requiring a re-initialization into a larger Bloom filter. Further, despite being dynamic, the current probabilistic representation does not allow for the removal edges from the graph. To support this, we could replace the Bloom filters with other probabilistic set representations that allow for item removal [Bender et al. 2012, Pan et al. 2014]. Lastly, an additional space improvement could be achieved with more space efficient probabilistic set representations such as compressed Bloom filters [Mitzenmacher 2001].
